5 Conclusion **9**

1 Introduction

Service-oriented computing (SOC) structures software as collections of interoperable, loosely coupled services, each exposing a well-defined interface independently of the underlying platform or implementation language. As distributed systems span organisational, geographic, and technology boundaries, the choice of communication paradigm has direct consequences for performance, security, developer experience, and long-term maintainability.

This report compares four paradigms that have shaped distributed systems over the past three decades. **SOAP/WSDL** emerged in the late 1990s as a standards-driven, XML-based messaging protocol accompanied by a formal interface contract. **REST** (Representational State Transfer) was formalised by Roy Fielding in 2000 as an architectural style aligned with HTTP semantics, enabling simple, cacheable, resource-oriented APIs. **GraphQL**, developed at Facebook in 2012 and open-sourced in 2015, introduced a typed query language that allows clients to specify precisely the data they require. **gRPC**, released by Google in 2016, uses Protocol Buffers over HTTP/2 for high-performance binary RPC communication with native streaming support.

The analysis evaluates each technology across eight dimensions: architecture and principles,

strengths, weaknesses, technology stack and data encoding, execution environments, security model, and use cases. Section 3 illustrates each technology with code examples using a common user management domain. Section 4 consolidates the comparison in a summary table, and Section 5 discusses when each approach is most suitable.

2 Technology Analysis by Dimension

2.1 SOAP / WSDL

Architecture and principles. SOAP (Simple Object Access Protocol) defines a strict XML-based message envelope composed of an optional *Header* — carrying metadata such as authentication tokens, routing directives, and transaction coordinators — and a mandatory *Body* carrying the operation payload. The protocol is transport-agnostic but deployed almost exclusively over HTTPS. Its companion specification, WSDL (Web Services Description Language), provides a machine-readable XML contract that formally describes operations, message schemas, and endpoint addresses, enabling automated client and server stub generation. The WS-* extension family adds WS-Security (XML Signature and XML Encryption for message-level integrity and confidentiality), WS-ReliableMessaging, and WS-AtomicTransaction. Services are tightly coupled: WSDL changes require coordinated updates across all consumers. Supported message exchange patterns include request-response, one-way, solicit-response, and notification.

Strengths. SOAP's defining advantage is its formalism. WS-Security provides end-to-end message-level security independent of transport: digital signatures ensure integrity and non-repudiation; selective encryption provides confidentiality across multi-hop intermediaries — a capability unique to SOAP in this comparison. The WSDL contract is machine-verifiable and supports automated code generation via Apache CXF, JAX-WS, and WCF. WS-AtomicTransaction enables distributed ACID transactions across organisational boundaries. These properties make SOAP the only technology suited to contexts where message-level guarantees carry regulatory weight.

Weaknesses. XML verbosity is the primary operational cost: envelopes inflate payload size, increase parsing latency, and complicate debugging. Despite formal standards, WS-* interoperability between different vendor implementations has been historically inconsistent. Browser and mobile support is minimal; debugging requires specialised XML tools rather than simple HTTP inspection. The overall complexity of the WS-* stack raises development costs and integration effort compared to every other option examined here.

Stack, security, environments, and use cases. Server implementations include Apache CXF and JAX-WS (Java), WCF (.NET), and Spyne (Python); messages are encoded in XML. Security is managed at message level via WS-Security, independently of TLS. SOAP is found primarily in banking, insurance, healthcare (HL7 v3), and government platforms where compliance, audit trails, and transactional guarantees are legally required. It is rarely the right choice for new projects outside these regulated contexts.

2.2 REST (Representational State Transfer)

Architecture and principles. REST is an architectural style — not a protocol — defined by six constraints applied to HTTP: client-server separation, statelessness, cacheability, uniform

interface, layered system, and optional code-on-demand. Applied to HTTP, these produce APIs where resources are identified by URIs and manipulated via standard verbs (GET, POST, PUT, PATCH, DELETE), with status codes providing a standardised outcome vocabulary. Statelessness requires each request to be self-contained, enabling horizontal scaling without session affinity. The dominant payload format is JSON, consumed by any language or platform without specialised tooling.

Strengths. Simplicity is REST's principal advantage. Any HTTP client — a browser, cURL, or a mobile SDK — can interact with a REST API without code generation. GET responses are cacheable at every HTTP layer (browser, CDN, reverse proxy), making REST exceptionally efficient for read-heavy workloads. The OpenAPI ecosystem provides standardised documentation, mock servers, validation, and multi-language client generation. REST's combination of accessibility and ecosystem depth makes it the most widely adopted paradigm for third-party API consumers.

Weaknesses. REST imposes no mandatory schema, leading to inconsistent API design quality. Over-fetching (endpoints return more data than needed) and under-fetching (multiple requests required to assemble a view) are structural limitations that are particularly costly for mobile clients. API versioning has no consensus strategy; URL versioning, header negotiation, and content negotiation each carry different trade-offs. There is no standard for message-level security.

Stack, security, environments, and use cases. Frameworks include Flask and Django REST Framework (Python), Spring Boot (Java), and Express.js (Node.js). Security relies on TLS for transport and OAuth2/JWT for authentication. REST is the standard for public APIs, cloud provider interfaces (AWS, GCP, Azure), SaaS platforms, and mobile backends. It is less appropriate for high-frequency internal microservice communication, where binary protocols offer better performance, or for clients with rapidly evolving and diverse data requirements.

2.3 GraphQL

Architecture and principles. GraphQL exposes a single endpoint backed by a strongly typed schema defined in the Schema Definition Language (SDL). Clients submit queries specifying precisely the fields required; the server responds with a payload mirroring the query structure. Three root operation types are defined: Query (read), Mutation (write), and Subscription (real-time events via WebSocket). Field resolution is delegated to resolver functions, which decouple the API schema from the underlying data sources and enable a single endpoint to aggregate data from multiple backends — a pattern known as backend-for-frontend (BFF).

Strengths. GraphQL eliminates both over-fetching and under-fetching simultaneously: the client declares exactly what it needs and the server returns only that. The typed schema functions as living documentation with interactive explorers (GraphiQL, Apollo Studio), compile-time query validation, and type-safe client code generation. A single query can retrieve data that would require several sequential REST requests, reducing network round trips. Schema introspection and strong typing significantly improve developer tooling and reduce integration errors.

Weaknesses. The N+1 query problem — where resolving N parent objects triggers N separate resolver calls for their children — requires the DataLoader batching pattern to avoid database

overload. HTTP caching is incompatible with the standard POST-to-single-endpoint model; persisted queries are needed as a workaround. Deeply nested queries create denial-of-service risk; query depth limits and complexity analysis are necessary safeguards. Schema evolution at scale demands careful deprecation management rather than simple version bumps.

Stack, security, environments, and use cases. Server implementations include Apollo Server (Node.js), Strawberry and Graphene (Python), graphql-java (Java), and gqlgen (Go). Security uses TLS and OAuth2/JWT; introspection must be disabled in production; field-level authorisation is implemented in resolvers. GraphQL is best suited to BFF layers serving diverse client populations, mobile applications with heterogeneous data requirements, and developer platforms where schema-driven tooling is valued. It is poorly suited to simple CRUD services with uniform clients or architectures where HTTP caching is a first-class concern.

2.4 gRPC

Architecture and principles. gRPC is a high-performance RPC framework using Protocol Buffers (protobuf) as both interface definition language and binary serialisation format. Services and messages are defined in `.proto` files; the `protoc` compiler generates typed client stubs and server base classes in the target language. The framework runs exclusively over HTTP/2, which provides multiplexed concurrent streams, binary framing, HPACK header compression, and flow control. Four communication patterns are natively supported: unary (one request, one response), server-streaming, client-streaming, and bidirectional streaming. From the application layer, invoking a remote service is syntactically identical to a local function call.

Strengths. Performance is gRPC's defining advantage. Protocol Buffer messages use field-number tags rather than field names, producing payloads three to ten times smaller than equivalent JSON, with faster serialisation and deserialisation. HTTP/2 multiplexing allows multiple concurrent RPCs over a single TCP connection without head-of-line blocking. Native streaming enables server-side data feeds, client telemetry aggregation, and full-duplex real-time communication — patterns that REST and GraphQL cannot replicate natively. Strong schema enforcement via `.proto` files eliminates serialisation mismatches, and code generation removes boilerplate across all supported languages.

Weaknesses. Binary encoding makes debugging without the schema file impossible; grpcurl and server reflection partially mitigate this. Browsers cannot use native gRPC because HTTP/2 trailers are inaccessible via browser APIs; gRPC-Web with an Envoy proxy layer is required. Protobuf schema evolution follows strict field-number permanence rules: numbers cannot be reused and type changes break binary compatibility, requiring disciplined schema management. The toolchain (protoc, plugins, schema registries) adds operational overhead compared to text-based alternatives.

Stack, security, environments, and use cases. Supported languages include Go, Java, Python, C++, C#, Node.js, and Kotlin via plugins. Security uses TLS for transport and mTLS for mutual identity verification in zero-trust architectures; authorisation is implemented via server-side interceptors. gRPC is the preferred choice for internal microservice communication, polyglot systems requiring consistent cross-language contracts, latency-sensitive workloads, ML inference serving (e.g. TensorFlow Serving), and IoT telemetry pipelines. It is unsuitable for browser-native clients without a proxy and for public APIs targeting third-party developers

unfamiliar with protobuf tooling.

3 Practical Examples

All examples use the same domain: a `UserService` that manages user records. This allows direct comparison at the protocol level. Complete Python server and client implementations for all four technologies are provided in the `examples/` directory of this project.

3.1 SOAP / WSDL

The WSDL excerpt below shows the type definitions and the operation contract. The `portType` element is the WSDL equivalent of an interface: it declares the `getUser` operation and the names of its input and output messages, each mapped to an XSD complex type.

```
<types>
  <xsd:complexType name="GetUserRequest">
    <xsd:sequence>
      <xsd:element name="userId" type="xsd:int"/>
    </xsd:sequence>
  </xsd:complexType>
  <xsd:complexType name="GetUserResponse">
    <xsd:sequence>
      <xsd:element name="userId"   type="xsd:int"/>
      <xsd:element name="username" type="xsd:string"/>
      <xsd:element name="email"    type="xsd:string"/>
      <xsd:element name="role"     type="xsd:string"/>
    </xsd:sequence>
  </xsd:complexType>
</types>
<portType name="UserPortType">
  <operation name="getUser">
    <input  message="tns:GetUserRequest"/>
    <output message="tns:GetUserResponse"/>
  </operation>
</portType>
```

Listing 1: WSDL excerpt — type definitions and operation contract

The SOAP envelopes below illustrate the XML framing that every message carries, regardless of payload size. The envelope wraps the actual business data (the user ID in the request, the four user fields in the response) in multiple layers of XML markup, which is the root cause of SOAP's bandwidth and parsing overhead.

```
<!-- REQUEST -->
<soapenv:Envelope xmlns:soapenv="http://schemas.xmlsoap.org/soap/envelope/"
                  xmlns:usr="http://example.com/userservice">
  <soapenv:Header/>
  <soapenv:Body>
    <usr:GetUserRequest><usr:userId>42</usr:userId></usr:GetUserRequest>
  </soapenv:Body>
</soapenv:Envelope>

<!-- RESPONSE -->
<soapenv:Envelope xmlns:soapenv="http://schemas.xmlsoap.org/soap/envelope/"
                  xmlns:usr="http://example.com/userservice">
```

```
  <soapenv:Body>
    <usr:GetUserResponse>
      <usr:userId>42</usr:userId>
      <usr:username>jdupont</usr:username>
      <usr:email>j.dupont@example.com</usr:email>
      <usr:role>editor</usr:role>
    </usr:GetUserResponse>
  </soapenv:Body>
</soapenv:Envelope>
```

Listing 2: SOAP request and response envelopes for getUser

3.2 REST

The two listings below show a resource retrieval (GET) and a resource creation (POST) with their respective responses. HTTP status codes and the `Location` header in the POST response carry semantic meaning without requiring any parsing of the body.

```
GET /api/users/42 HTTP/1.1
Host: api.example.com
Authorization: Bearer eyJhbGciOiJSUzI1NiJ9...

HTTP/1.1 200 OK
Content-Type: application/json

{"userId":42,"username":"jdupont","email":"j.dupont@example.com","role":"
    editor"}
```

Listing 3: GET /api/users/42 — request and response

```
POST /api/users HTTP/1.1
Content-Type: application/json

{"username":"mmartin","email":"m.martin@example.com","role":"viewer"}

HTTP/1.1 201 Created
Location: /api/users/43
Content-Type: application/json

{"userId":43,"username":"mmartin","email":"m.martin@example.com","role":"
    viewer"}
```

Listing 4: POST /api/users — resource creation

3.3 GraphQL

The SDL schema defines the complete type system. The query below requests only three fields (`username`, `email`, and the nested post titles), leaving `userId`, `role`, and `createdAt` unselected. The response mirrors the query structure exactly: unrequested fields are absent, and the user's posts are returned in the same round trip — eliminating both over-fetching and under-fetching simultaneously.

```
type User {
  userId: ID!   username: String!   email: String!
  role: String!   createdAt: String!   posts: [Post!]!
```

```
}
type Post   { postId: ID!   title: String!   publishedAt: String! }
type Query  { user(userId: ID!): User   users: [User!]! }
type Mutation { createUser(username: String!, email: String!, role: String!):
     User! }
type Subscription { userCreated: User! }
```

Listing 5: GraphQL schema (SDL)

```
// Query (sent as HTTP POST body)
query GetUserWithPosts {
  user(userId: "42") {
    username
    email
    posts { title  publishedAt }
  }
}

// Response
{
  "data": {
    "user": {
      "username": "jdupont",
      "email": "j.dupont@example.com",
      "posts": [
        {"title": "Comparing API Paradigms", "publishedAt": "2026-02-01T14
    :30:00Z"}
      ]
    }
  }
}
```

Listing 6: GraphQL query and server response

3.4 gRPC

The `.proto` file is the authoritative contract for the service. The Python server listing implements the three RPCs: two unary calls and one server-streaming call. The client listing demonstrates invoking the streaming `ListUsers` RPC, which yields user records one by one over an open HTTP/2 stream.

```
syntax = "proto3";
package userservice;

service UserService {
  rpc GetUser    (GetUserRequest)    returns (UserResponse);
  rpc ListUsers  (ListUsersRequest)  returns (stream UserResponse);
  rpc CreateUser (CreateUserRequest) returns (UserResponse);
}

message GetUserRequest    { int32  user_id  = 1; }
message ListUsersRequest  {}
message CreateUserRequest { string username = 1; string email = 2; string
    role = 3; }
message UserResponse      { int32  user_id  = 1; string username = 2;
```

```
                                string email     = 3; string role      = 4; }
```

Listing 7: user_service.proto — service contract

```python
class UserServiceServicer(user_service_pb2_grpc.UserServiceServicer):

    def GetUser(self, request, context):
        user = USERS.get(request.user_id)
        if user is None:
            context.abort(grpc.StatusCode.NOT_FOUND, "User not found")
        return user_service_pb2.UserResponse(user_id=request.user_id, **user
    )

    def ListUsers(self, request, context):        # server-streaming RPC
        for uid, user in USERS.items():
            yield user_service_pb2.UserResponse(user_id=uid, **user)

    def CreateUser(self, request, context):
        nid = max(USERS) + 1
        USERS[nid] = dict(username=request.username,
                          email=request.email, role=request.role)
        return user_service_pb2.UserResponse(user_id=nid, **USERS[nid])
```

Listing 8: gRPC server — servicer implementation (Python)

```python
with grpc.insecure_channel("localhost:50051") as channel:
    stub = user_service_pb2_grpc.UserServiceStub(channel)

    # Unary call: retrieve a single user
    r = stub.GetUser(user_service_pb2.GetUserRequest(user_id=42))
    print(f"GetUser -> {r.username}, {r.role}")

    # Server-streaming call: iterate over all users as they arrive
    for u in stub.ListUsers(user_service_pb2.ListUsersRequest()):
        print(f"  [{u.user_id}] {u.username} <{u.email}>")
```

Listing 9: gRPC client — unary and streaming calls (Python)

4 Comparative Summary Table

Dimension	SOAP / WSDL	REST	GraphQL	gRPC
Protocol / transport	SOAP over HTTP, SMTP, JMS	HTTP/1.1 or HTTP/2	HTTP (POST / GET)	HTTP/2 only
Message format	XML (mandatory)	JSON (typical)	JSON	Protocol Buffers (binary)
Schema / contract	WSDL (mandatory)	OpenAPI (optional)	SDL (mandatory)	.proto (mandatory)
Performance	Low — verbose XML	Moderate	Moderate	High — binary + HTTP/2
Payload size	Very large	Medium	Client-controlled	Very small
Data fetching model	Fixed per operation	Fixed per endpoint	Client-defined fields	Fixed per RPC

Dimension	SOAP / WSDL	REST	GraphQL	gRPC
Streaming support	Limited (MTOM)	Partial (SSE)	Subscriptions (WS)	Native (4 patterns)
Browser support	Poor	Excellent	Excellent	Limited (gRPC-Web)
Security model	WS-Security (msg-level)	TLS + OAuth2 / JWT	TLS + OAuth2 / JWT	TLS + mTLS
Developer usability	Low (steep learning curve)	High	High (with tooling)	Moderate
Code generation	Yes (from WSDL)	Partial (from OpenAPI)	Yes (from SDL)	Yes (from .proto)
HTTP caching	Not applicable	Native (GET responses)	Persisted queries	Application-level only
Client–server coupling	Tight	Loose	Loose (schema-guided)	Tight (schema-governed)
Versioning strategy	WSDL versioning	URL / header versioning	Additive schema evolution	Field-number stability
Typical domain	Enterprise, banking, HL7	Public APIs, SaaS, mobile	BFF, SPA, mobile	Microservices, IoT, ML
Ecosystem maturity	Very mature (largely legacy)	Very mature	Maturing rapidly	Maturing

5 Conclusion

The four technologies examined in this report are not competing alternatives but complementary tools, each suited to a distinct set of requirements. Selecting the wrong paradigm has real costs — wasted bandwidth, poor developer experience, or security gaps — while selecting the right one can significantly simplify both implementation and operations.

SOAP remains the appropriate choice when formal contractual guarantees, message-level security, or distributed transactional semantics carry legal or compliance weight. In banking, insurance, and healthcare integration, these properties are not optional, and SOAP's complexity is the price of the guarantees it provides.

REST is the rational default for any API that will be consumed by diverse, externally managed clients. Its alignment with HTTP semantics, universal tooling support, and native caching behaviour make it the most accessible and operationally simple option. Its limitations around schema enforcement and data fetching efficiency are real but manageable for the majority of public API use cases.

GraphQL addresses REST's data fetching limitations in a principled way. Its ability to serve multiple client types from a single schema and to aggregate multiple backends into one query layer makes it the natural choice for frontend-facing data layers in complex applications. The server-side complexity it introduces is a reasonable trade-off when clients are diverse and network efficiency matters.

gRPC represents the highest-performance option and is the appropriate choice for internal service-to-service communication in polyglot microservice architectures. Its binary encoding, HTTP/2 transport, native streaming, and cross-language code generation provide advantages

that text-based protocols cannot match for high-frequency, low-latency communication. The accessibility trade-offs — binary opacity, limited browser support, protobuf toolchain overhead — are acceptable when teams control both ends of the connection.

In practice, mature distributed systems commonly employ all four paradigms simultaneously: REST for the public API surface, GraphQL for the frontend aggregation layer, gRPC for internal service communication, and SOAP where legacy integration requirements demand it. Understanding the reasoning behind each technology, rather than treating any single one as a universal solution, is the foundation of sound distributed systems engineering.
